Phylogenetic distribution and evolution of mycorrhizas in land plants

Received: 22 June 2005 / Accepted: 15 December 2005 / Published online: 6 May 2006
© Springer-Verlag 2006

Abstract A survey of 659 papers mostly published since 1987 was conducted to compile a checklist of mycorrhizal occurrence among 3,617 species (263 families) of land plants. A plant phylogeny was then used to map the mycorrhizal information to examine evolutionary patterns. Several findings from this survey enhance our understanding of the roles of mycorrhizas in the origin and subsequent diversification of land plants. First, 80 and 92% of surveyed land plant species and families are mycorrhizal. Second, arbuscular mycorrhiza (AM) is the predominant and ancestral type of mycorrhiza in land plants. Its occurrence in a vast majority of land plants and early-diverging lineages of liverworts suggests that the origin of AM probably coincided with the origin of land plants. Third, ectomycorrhiza (ECM) and its derived types independently evolved from AM many times through parallel evolution. Coevolution between plant and fungal partners in ECM and its derived types has probably contributed to diversification of both plant hosts and fungal symbionts. Fourth, mycoheterotrophy and loss of the mycorrhizal condition also evolved many times independently in land plants through parallel evolution.

Keywords Mycorrhizas · Land plants · Fungi · Parallel evolution

Introduction

Mycorrhizas, dual organs of absorption formed when symbiotic fungi inhabit healthy tissues of most terrestrial plants (Trappe 1996), have widespread occurrence among land plants and are increasingly believed to have played an important role in the successful colonization of the land by

plants (Pirozynski and Malloch 1975; Malloch et al. 1980; Harley and Harley 1987; Trappe 1987; Selosse and Le Tacon 1998; Read et al. 2000; Brundrett 2002). Since Nägeli first described them in 1842 (see Koide and Mosse 2004), only a few major surveys have been conducted on their phylogenetic distribution in various groups of land plants either by retrieving information from literature or through direct observation (Trappe 1987; Harley and Harley 1987; Newman and Reddell 1987). Trappe (1987) gathered information on the presence and absence of mycorrhizas in 6,507 species of angiosperms investigated in previous studies and mapped the phylogenetic distribution of mycorrhizas using the classification system by Cronquist (1981). He found that 82% of the species were mycorrhizal. From the occurrence of various types of mycorrhizas in different subclasses and orders of angiosperms, he further inferred that the ancestral type was glomeromycetous (the original word “zygomycetous” is not used because fungi forming this type of mycorrhiza are now placed in the new phylum Glomeromycota, see Schüssler et al. 2001) mycorrhiza, and ascomycetous and basidiomycetous mycorrhizas belong to the derived types, and that evolution of mycorrhizas in plants had progressed from obligate to facultative mycorrhizas and ultimately to nonmycorrhizas. In the same year, Harley and Harley (1987) published a checklist of the mycorrhizal status of 144 families of vascular plants in the British flora, documenting various types of mycorrhizas in an entire flora for the first time. More recently, Gemma et al. (1992) and Zhao (2000) investigated the mycorrhizal status of 89 and 256 species of pteridophytes in Hawaii and Yunnan, China, respectively. They found that the percentages of mycorrhizal species in pteridophytes (74 and 33%, respectively) were lower than in angiosperms as reported by Trappe (1987). Whether bryophytes have mycorrhizas or not is still a debatable issue, but many liverworts and hornworts have fungal associations (Read et al. 2000). In two surveys of British liverworts, Pocock and Duckett (1985) and Duckett et al. (1991) reported that among the 206 and 284 examined species, respectively, 16% contained fungal endophytes in their rhizoids or thalli.

Mycorrhizal research has advanced at an astonishing pace over the last two decades due to a recent surge of interest in

the subject by botanists, mycologists, and ecologists. A large number of new reports on mycorrhizal occurrence in land plants, especially in pteridophytes and liverworts, have been published since the surveys by Trappe (1987) and Harley and Harley (1987). During the same period, our understanding of the land plant phylogeny was greatly improved through major efforts by molecular systematists. An explicit phylogenetic classification system of angiosperms is now available (Stevens 2004), and a nonflowering land plant phylogeny will be published soon (Qiu et al. unpublished data). Hence, reviewing mycorrhizal occurrence in land plants and mapping this information onto the newly available plant phylogeny will update our knowledge on mycorrhizal abundance in plants, facilitate examination of the origin and evolutionary pattern of mycorrhizal symbiosis in land plants, and enhance our understanding of this important biological interaction and its impact on evolution of both plants and fungi. Areas that require further study, especially the taxa that occupy critical positions in the land plant phylogeny and for which mycorrhizal information is still lacking, can also be identified through these efforts.

Materials and methods

In this review, we compiled information on mycorrhizal occurrence in land plants mostly from the papers published since 1987, as those published before were reviewed by Trappe (1987) and Harley and Harley (1987). First, a library consisting of 4,193 mycorrhiza-related references was established. After browsing the abstracts, 961 references that provided information on mycorrhizal occurrence in plant species from all the continents and all major habitats were selected. Due to time limitation and unavailability of some literature, 659 of these 961 references are reviewed here. Data on mycorrhizal status of each plant species were extracted from these references, based on whether the species was mycorrhizal or not, and if so, what type. An updated mycorrhizal classification system proposed by Smith and Read (1997) was used here. Seven types of mycorrhizas were all recognized (see the footnote b in Table 1), along with nonmycorrhiza and mycoheterotrophy. A species is considered to be obligately mycorrhizal if it is always found to form mycorrhiza, while a species is considered to be facultatively mycorrhizal if it is reported to form mycorrhizas in one habitat but not in another. If a plant species can form different kinds of mycorrhizas simultaneously or in different habitats, it is recorded as forming all relevant mycorrhizal types. All the data are presented in Table 1, which groups all the examined plant species into families that are further arranged according to the land plant phylogeny used in this study (Stevens 2004; Qiu et al. unpublished). The family definition for vascular plants generally follows Mabberley (1987), but for a small number of newly recognized families, the nomenclature of Stevens (2004) is used. For liverworts, the system by Grolle (1983) for family definition is followed. The data from Harley and Harley (1987), containing 1,101 species, were added to this table, but those of Trappe (1987) were not as they were not published.

The information in Table 1 was then mapped onto a land plant phylogeny drawn according to a multigene analysis of nonflowering land plants (Qiu et al. unpublished) and the angiosperm classification system proposed by Stevens (2004). Family was used as the unit of reconstruction (i.e., terminal node) in this phylogeny. For each family, the percentages of obligate, facultative, and nonmycorrhizal species, and the percentage of each type of mycorrhizas among all mycorrhizal species were calculated and plotted onto the land plant phylogeny.

One major improvement of this review over those by Trappe (1987) and Harley and Harley (1987) is the use of a rigorously reconstructed land plant phylogeny to map the mycorrhizal information down to the family level for a worldwide coverage. Trappe (1987) covered only angiosperms, whereas Harley and Harley (1987) surveyed only the British vascular flora. Cronquist's (1981) classification system of angiosperms used by Trappe (1987) has been significantly revised by molecular systematists (Soltis et al. 2000; Stevens 2004). Another major improvement is that information on mycorrhizal occurrence, more precisely fungal association in bryophytes, is included for the first time. Hence, this review should allow a thorough examination of origin and evolution of mycorrhizal symbiosis in land plants.

Results and discussion

A total of 3,617 species from 263 families of land plants were covered in this survey of mycorrhizal status (Tables 1 and 2). For land plants as a whole, 80% of the recorded species and 92% of the families are mycorrhizal. When broken into four traditionally delimited groups (angiosperms, gymnosperms, pteridophytes, and bryophytes), these percentages vary from group to group. In angiosperms, the most species-rich clade of land plants and the dominant group in most terrestrial plant communities, 85 and 94% of species and families are mycorrhizal. These numbers are similar to those reported by Trappe (1987), whose study included more than twice as many species as this one. All of the 84 species of gymnosperms surveyed here are mycorrhizal, and almost all of them are obligately mycorrhizal. These two aspects of mycorrhizal status in gymnosperms highlight the essential role that mycorrhizas play in the life of these plants, which generally grow in nutrient-poor environments. For pteridophytes, 52 and 93% of the species and families are mycorrhizal. Finally, 46 and 71% of the bryophyte species and families have fungal associations.

When this body of information is projected in a plant phylogenetic perspective (Fig. 1), the origin and evolutionary patterns of mycorrhizas in land plants become quite clear. Below, we discuss these various aspects of mycorrhizal evolution in plants.

^aThe families in column 1 are divided into four groups: bryophytes, pteridophytes, gymnosperms and angiosperms. For each group, the order of families is consistent with the phylogeny used in Fig. 1

^bThe mycorrhizal types shown in column 2 are consistent to the current widely used system of Smith and Read (1997): *AM* arbuscular mycorrhiza, *ECM* ectomycorrhiza, *EEM* ectendomycorrhiza, *ORM* orchid mycorrhiza, *ERM* ericoid mycorrhiza, *MTM* monotropoid mycorrhiza, *ABM* arbutoid mycorrhiza, as well as *NM* nonmycorrhiza, and mycoheterotrophy

^cFor the bryophytes, fungal associations were used instead of mycorrhiza; *A*, *B*, and *G* indicate ascomycetous, basidiomycetous, and glomeromycetous fungal associations, respectively

mosses (Fig. 1; but see Boullard 1988 for mycorrhizoids in *Takakia*), tends to suggest that these plant–fungus interactions began when land plants originated. At present, there is no doubt that bryophytes preceded vascular plants during early evolution of land plants (Kenrick and Crane 1997).

Table 1 (continued)

656. Brundrett MC (2002) *New Phytol* 154:275–304 (Also see the author's website: Introduction to mycorrhizas. [WWW document] URL: <http://www.ffp.csiro.au/research/mycorrhiza/>)

Furthermore, liverworts are clearly favored as the earliest divergent lineage of extant land plants according to emerging molecular evidence (Qiu et al. 1998; Dombrowska and Qiu 2004; Groth-Malonek et al. 2005; Qiu et al. unpublished), despite some lingering controversy on relationships among three bryophyte lineages: liverworts, mosses, and hornworts (see Qiu and Lee 2000; Renzaglia et al. 2000). Hence, the widespread occurrence of fungal association in liverworts deserves some attention here.

Mycorrhizas, or more precisely mycorrhizoids and mycothalli, are found in many of the liverworts that have been investigated (Pocock and Duckett 1985; Boullard 1988; Duckett et al. 1991). Several aspects of these symbioses revealed by recent studies may help clarify their evolutionary relationship to mycorrhizas in vascular plants. First, in cases where detailed ultrastructural analysis has been done, structures similar to those in the endomycorrhizas of vascular plants, i.e. arbuscules, have been observed in some liverworts (Read et al. 2000; Carafa et al. 2003; Russell and Bulman 2005). Second, cross-inoculation experiments have convincingly demonstrated that the same fungi can infect both liverworts and angiosperms and produce similar structures for either glomeromycetous or ascomycetous mycorrhizas (Read et al. 2000). Third, although isotopic tracing of nutrient, water, and carbon exchange has not been done for most liverwort–fungus symbioses, the carbon flow from *Betula* through the ectomycorrhizal fungus *Tulasnella* to the mycoheterotrophic liverwort *Cryptothallus* has been confirmed by a ¹⁴C feeding experiment (Bidartondo et al. 2003). Finally, the evolutionary pattern of plant–fungus symbiosis observed in angiosperms by Trappe (1987) and in vascular plants (this study), i.e., glomeromycetous mycorrhizas being the common type and occurring in early-diverging plant lineages and ascomycetous and basidiomycetous mycorrhizas being the rare type and found in late-evolving plant lineages, is also seen in liverworts (Fig. 1). These four lines of evidence indicate that even though the plant structures involved in symbiosis are probably structurally and functionally analogous between liverworts and vascular plants, the nature of the biological interaction is almost certain to be evolutionarily homologous. Besides further investigations of the functional aspects of mycorrhizas in liverworts and other bryophytes as suggested by Read et al. (2000), one line of evidence that will provide conclusive support for evolutionary homology between the mycorrhizal symbioses in bryophytes and vascular plants could come from studies of plant genes that are involved in the processes, some of

Table 2 Mycorrhizal investigation of four major groups of land plants at both family and species levels

Group	Total number of families/species surveyed	No. (%) of mycorrhizal families (obligate and facultative)	No. (%) of obligately mycorrhizal species	No. (%) of facultatively mycorrhizal species	No. (%) of nonmycorrhizal families	No. (%) of nonmycorrhizal species
Bryophytes	28/143	20 (71%)	60 (42%)	6 (4%)	8 (29%)	77 (54%)
Pterophytes	28/426	26 (93%)	185 (43%)	39 (9%)	2 (7%)	202 (47%)
Gymnosperms	12/84	12 (100%)	83 (99%)	1 (1%)	0 (0%)	0 (0%)
Angiosperms	195/2,964	184 (94%)	2,141 (72%)	396 (13%)	11 (6%)	427 (14%)

which have been identified in recent studies (Stracke et al. 2002; Liu et al. 2003; Ane et al. 2004; Demchenko et al. 2004; Levy et al. 2004). If the same genes are found to control development of mycorrhizas in all groups regardless of their expression in the gametophytes of bryophytes or the sporophytes of vascular plants, and if the gene phylogenies are congruent to the plant phylogeny, the final doubt about homology of the two types of symbioses will be dispelled.

If the mycorrhizal symbiosis in liverworts, other bryophytes, such as the moss *Takakia* (see Boulard 1988), and hornworts proves to be homologous to that in vascular plants, it becomes obvious that mycorrhiza was indeed an important means of water and nutrient uptake adopted by the earliest land plants (Pirozynski and Malloch 1975). Fossil evidence is in agreement with such a scenario. Both glomeromycetous fungi (Redecker et al. 2000) and liverworts (Wellman et al. 2003) evolved by the Ordovician, when plants colonized the land (Kenrick and Crane 1997). Fossil mycorrhizas formed between nonseptate fungi and the protracheophyte *Aglaophyton major* have been uncovered from the Rhynie chert, confirming that this type of plant–fungus interaction existed at least 400 million years ago (Remy et al. 1994; Kerp et al. 2004; Taylor et al. 2005). It is possible that evolution of mycorrhiza might even have predated the origin of land plants, if fungal association in the extinct charophyte *Palaeonitella* (Taylor et al. 1992) is mycorrhizal. We conclude that although more work is needed to solidify the relationship between mycorrhizal symbioses in bryophytes and vascular plants, including morphological, physiological, and molecular characterization of the plant–fungus interactions in both bryophytes and early vascular plants (see Read et al. 2000), all available evidence seems to point to an origin of mycorrhizas at the beginning of land plant evolution.

Arbuscular mycorrhiza is the ancestral type of mycorrhiza

When the different types of mycorrhizas are mapped onto the land plant phylogeny, it becomes clear that arbuscular mycorrhiza (AM), the endomycorrhiza formed by glomeromycetous fungi and plants, is the ancestral type, as it occurs in a vast majority of plants and in all early-diverging lineages of major clades of land plants (Fig. 1). Even in

bryophytes where the plant structures involved in symbiosis are rhizoids and thalli of the gametophyte, glomeromycetous fungi-mediated symbiosis results in formation of AM-like structures and is found in most early-diverging lineages of liverworts and in hornworts (Ligrone and Lopes 1989; Read et al. 2000; Russell and Bulman 2005). These two aspects of AM symbiosis suggest that the genetic mechanism underlying interaction between the plants and glomeromycetous fungi might have been established in the common ancestor of all land plants. Future molecular studies should be able to test this hypothesis to determine if the same genes are involved in plants–glomeromycetous fungi symbioses throughout land plants.

Trappe (1987) reported that AM is the ancestral type of mycorrhiza in angiosperms. Our survey, which broadens the scope to include all land plants, extends this conclusion to all land plants. This result is not likely to change even if relationships among three bryophyte lineages and vascular plants are altered (see Qiu and Lee 2000) because all of their early-diverging lineages possess AM when they are mycorrhizal. Furthermore, fossil evidence clearly indicates that AM is the most ancient type of mycorrhiza. The Devonian protracheophyte *Aglaophyton major* provides the best fossil record for existence of AM-like symbiosis as early as 400 million years ago; the arbuscules are visible in the protosteles of this early Devonian plant (Remy et al. 1994; Taylor et al. 2005). Fossil roots of younger age from the Triassic show that this type of symbiosis has been present continuously in early land plant evolution (Stubblefield et al. 1987). On the other hand, the oldest ectomycorrhizal fossils have so far been found only in the middle Eocene (50 million years ago) (LePage et al. 1997). The fossil record of glomeromycetous fungi, found in the Ordovician (Redecker et al. 2000), also clearly predates that of ascomycetous fungi unearthed from the Lower Devonian (Taylor et al. 1999). Given all these lines of evidence, it seems safe to conclude that AM represents the ancestral type of mycorrhiza in land plants.

Many independent conversions of arbuscular mycorrhiza to other types of mycorrhizas

If the ancestral state of AM in land plants is accepted, and further, if it can be agreed upon that the glomeromycetous fungi–plant interaction is underpinned by a genetic mech-

anism that has been stably inherited since its establishment in the common ancestor of all land plants, the phylogenetic distribution of AM and other types of mycorrhiza shown in Fig. 1 leads to the conclusion that there have been many independent conversions of AM to these other types of mycorrhizas. Brundrett (2002) previously proposed these evolutionary changes. In this review, we find overwhelming evidence in support of this hypothesis. Many plant lineages, ranging from pteridophytes through gymnosperms to angiosperms, contain some species that can form both AM and other types of mycorrhizas, e.g., Dryopteridaceae, Pinaceae, Gnetaceae, Araucariaceae, Cupressaceae, Orchidaceae, Cyperaceae, Poaceae, Ranunculaceae, Polygonaceae, Caryophyllaceae, Ericaceae, Rubiaceae, Oleaceae, Aquifoliaceae, Campanulaceae, Goodeniaceae, Asteraceae, Caprifoliaceae, Grossulariaceae, Myrtaceae, Melastomataceae, Euphorbiaceae, Salicaceae, Polygalaceae, Fabaceae, Rosaceae, Rhamnaceae, Juglandaceae, Betulaceae, Casuarinaceae, Cistaceae, Malvaceae, and Sapindaceae (Table 1; Fig. 1). These species might be in a transitional state from AM to other types of mycorrhizas. These other types of mycorrhizas have probably evolved as a consequence of emergence of new lineages in fungi on one side (e.g., certain groups of Ascomycetes and Basidiomycetes) and in plants on the other side (e.g., Pinaceae, Orchidaceae, Ericaceae, Fagales, and Malvales), and the associations formed by these new lineages that were able to colonize habitats that were previously not very successfully occupied by AM plants (Malloch et al. 1980). Because these other types of mycorrhizas have been classified using both morphological and plant partner criteria (Smith and Read 1997), we follow this classification in our discussion below.

Ectomycorrhiza

Ectomycorrhiza (ECM) is a partnership between mostly basidiomycetous fungi and various groups of land plants. It primarily occurs in Pinaceae, Araucariaceae, Cupressaceae, Gnetaceae, Polygonaceae, Nyctaginaceae, Myrtaceae, Salicaceae, Fabaceae, Fagales, and Malvales. In addition, many other families of vascular plants contain a small percentage of species that form this type of mycorrhiza. Most leafy liverworts also have ascomycetous and basidiomycetous fungal associations (Table 1; Fig. 1). Although ECM is much rarer than AM in land plants, among all types of mycorrhizas formed by ascomycetous and basidiomycetous fungi, it is the most common one. When viewed in a plant phylogenetic perspective, the distribution of ECM clearly suggests many independent origins of this type of mycorrhiza because its occurrence is sporadic throughout land plants and it is mostly found in derived lineages in major plant clades. Previously, Bruns and Shefferson (2004) estimated at least 12 independent origins of ECM within angiosperms by mapping ectomycorrhizal information provided in Smith and Read (1997) onto an angiosperm phylogeny (Soltis et al. 2000). Fitter and Moyersoen (1996) conducted a similar survey and reached a similar

conclusion. Our study revealed many more events of evolution of this type of mycorrhiza in land plants (Fig. 1).

Examination of the evolutionary histories of both plants and fungi may provide some ideas to understand how this type of mycorrhiza evolved repeatedly. The plants that form ECM typically grow in nutrient-poor environments, e.g., temperate and timberline forests of both Southern and Northern Hemispheres (Malloch et al. 1980), the spruce–hemlock–redwood forest of the coastal fog belt in the Pacific Northwestern USA, the wet eucalyptus forest in Australia, and the wet dipterocarp forest of Australasia (J. Trappe, personal communication). Phylogenetically, these plants represent derived lineages of some major land plant clades that once lived in a less nutrient-deficient environment, e.g., Pinaceae and Cupressaceae, as opposed to other conifers such as Cephalotaxaceae, Taxaceae, and Taxodiaceae, and Fagales and some Malvales vs other rosids. Meanwhile, the fungal species that participate in ECM symbiosis evolved repeatedly from saprotrophic homobasidiomycetes and also reverted to free-living condition many times independently (Hibbett et al. 2000), and they also represent derived lineages of fungi as a whole (Lutzoni et al. 2004). Thus, evolution of ECM could be viewed as an adaptation by those major plant clades to the change of environment when the climate on earth became more seasonal and arid (Hickey and Doyle 1977; Malloch et al. 1980), which immobilized nutrients, or simply as an adaptation to the environments that were limited in nutrient availability. From these considerations, it may be argued that the plasticity exhibited by ECM evolution reflects the opportunistic nature of a collective response by both plant and fungal partners to environmental challenges. This seems to be a short-term evolutionary strategy in comparison to AM, which clearly represents a major evolutionary innovation to solve a permanent water-and-nutrients deficiency problem faced by plants when they first made the virtually irreversible invasion onto the land in the Ordovician.

Fig. 1 A phylogenetic tree of 263 land plant families mapped with mycorrhizal information. **a** Non-angiosperms (including bryophytes, pteridophytes, and gymnosperms), **b** angiosperms except core eudicots, **c** core eudicots except rosids, and **d** rosids. For each family, the number in the column *Total* shows the total number of examined species; the *M%* column shows the percentage of obligately mycorrhizal species. The *FM%* column shows the percentage of facultatively mycorrhizal species, and the *NM%* column shows the percentage of nonmycorrhizal species. *Thicker terminal branches* were used to indicate 21 nonmycorrhizal families. For each of the 242 mycorrhizal families, the percentages of different types of mycorrhizae among all mycorrhizal species are shown in the *M type* column. The mycorrhizal types are consistent to the current widely used system of Smith and Read (1997): *AM* arbuscular mycorrhiza, *ECM* ectomycorrhiza, *EEM* ectendomycorrhiza, *ORM* orchid mycorrhiza, *ERM* ericoid mycorrhiza, *MTM* monotropoid mycorrhiza, *ABM* arbutoid mycorrhiza, as well as mycoheterotrophy. For the bryophytes, fungal associations were used instead of mycorrhiza: *A*, *B*, and *G* indicate ascomycetous, basidiomycetous, and glomeromycetous fungal associations, respectively. ^①Families in which ectomycorrhizal species have been reported. ^②Families in which mycoheterotrophic species have been reported

Fig. 1 (continued)**d**

The very different evolutionary pattern of ECM from that of AM might suggest a different underlying genetic mechanism. Also, the structure is quite different between the two types of mycorrhizas. In ECM, the fungal hyphae do not penetrate the cell wall, and instead form a Hartig net (an intercellular meshwork in the root epidermis and cortex) and a sheath around the root derived from this net. On the other hand, the fungal hyphae in AM penetrate the cell wall and often form arbuscules. At present, little is known about the molecular genetic basis of ECM development. All plant genes involved in mycorrhizal symbiosis identified so far control AM development (Stracke et al. 2002; Liu et al. 2003; Ane et al. 2004; Demchenko et al. 2004; Levy et al. 2004). One of these genes has a homolog in the moss *Physcomitrella patens* and several other early land plants (Wang and Qiu, unpublished data). Hence, it can be inferred that there might be a general genetic program in plants that mediates plant–fungus interaction, a small portion of which might even be involved in plant–fungal pathogen interaction as well (Harrison 1999). This program was most likely established at the beginning of land plant evolution, if not earlier, and mostly targets glomeromycetous fungi. It has been inherited in land plants since its inception and is responsible for the prevalence of AM seen today. When ECM evolved in a particular plant lineage, the homobasidiomycetous fungi might have adopted much of this general genetic program, but also modified some aspects of it to suit a slightly different plant–fungus partnership. One intriguing question is how different plant lineages, particularly those as diverse as ferns, gymnosperms, and angiosperms, adapted the general genetic program for ECM development, as the structures of mycorrhizas are apparently very similar between these diverse lineages. Perhaps different genes are involved in each case, thus, the host specificity developed with different fungal symbionts in each case of ECM (as opposed to AM). Indeed, difference in gene expression was observed to be related to host specificity (Le Quere et al. 2004). Future work will likely reveal more details to help us understand how many independent conversions of ECM from AM had occurred.

The ericaceous mycorrhizas and their close relationship to ectomycorrhiza

There are six types of mycorrhizas in Ericaceae. With the exception of AM, five of them are partnerships between ascomycetous or basidiomycetous fungi and plants: ECM, ectendomycorrhiza (EEM), arbutoid mycorrhiza (ABM), monotropoid mycorrhiza (MTM), and ericoid mycorrhiza (ERM). Among these five types, ECM occurs in many plant lineages outside of Ericaceae (see above), and EEM is found in Pinaceae, Araucariaceae, Ericaceae, Salicaceae, Fabaceae, Betulaceae, and Cistaceae (Fig. 1). ABM, MTM, and ERM can be deemed to be genuinely ericaceous mycorrhizas, as they occur almost exclusively in this family. The only exception is ERM, which has also been found in Diapensiaceae, a close relative of Ericaceae. The

ericaceous mycorrhizas share many characteristics with ECM, but exhibit a high degree of intracellular penetration (Smith and Read 1997). Brundrett (2002) suggested that ABM, MTM, and ERM were derived from ECM. Our mapping of ECM and these other types of mycorrhizas onto the land plant phylogeny and examination of their distribution within Ericaceae supports this interpretation. Further, we add that EEM probably represents a transitional stage between ECM and the three types of ericaceous mycorrhizas, ABM, MTM, and ERM, as ECM and EEM are found only in the basal lineages of Ericaceae, Monotropoideae, and Arbutoideae (Kron et al. 2002).

Previous studies have identified the fungal symbionts of the ericaceous mycorrhizas. One interesting phenomenon is that the fungal strains isolated from these three types of mycorrhizas can also form ECM with other plant species (reviewed by Smith and Read 1997). This observation strongly suggests a close relationship between ECM and the ericaceous mycorrhizas. An interesting question that arises is why the same fungi cannot penetrate into root cells of ectomycorrhizal hosts yet are able to do so with ericaceous plants. One answer could be that host plants play an important role in controlling development of different types of mycorrhizas.

Orchid mycorrhiza

Orchid mycorrhiza (ORM) is generally thought to be restricted to the Orchidaceae, which involve mostly basidiomycetous fungi (Leake 1994). Occurrence of this type of mycorrhiza in other plants such as the subterranean nonphotosynthetic liverwort *Cryptothallus mirabilis* (Ligrone et al. 1993; Bidartondo et al. 2003) and the monocot *Thismia* sp. (Brundrett 2002 see <http://www.ffp.csiro.au/research/mycorrhiza/>) probably represents functional and structural convergence, as the fungal partners are of different types than those of the true ORM in Orchidaceae (Leake 1994). In this perspective, ORM, like the ericaceous mycorrhizas discussed above, can be considered to occur exclusively in one plant family, Orchidaceae, and probably represents a highly specialized type of ectomycorrhiza. One fact supporting this idea is that some species of lower Epidendroideae, an early-diverging lineage within Orchidaceae (Cameron et al. 1999), still have ECM (Bidartondo et al. 2004; Selosse et al. 2004).

Did evolution of ectomycorrhiza and its derived types of mycorrhizas spur diversification of plant lineages that harbor these symbiotic systems?

If AM was instrumental in the origin and subsequent diversification of land plants in a newly exploited niche, did evolution of ECM and its derived types of mycorrhizas, which involve Ascomycetes and Basidiomycetes, contribute to diversification of plant lineages that forged these new partnerships? Our review provides a rather positive

answer to this question. In plant families where ECM and its derivatives are the main types of mycorrhizas or account for a significant percentage (>20%), e.g., Pinaceae, Orchidaceae, Nyctaginaceae, Polygonaceae, Ericaceae, Aquifoliaceae, Salicaceae, Fagaceae, Betulaceae, Cistaceae, Dipterocarpaceae, Myrtaceae, and Melastomataceae (Mabberley 1987), the species number is often high to very high in comparison to their close relatives that have AM (Fig. 1). In the case of woody plants, the members of these families are often dominant species in their communities (Malloch et al. 1980). Although there are many factors that may affect speciation rate, we believe that the correlation between high occurrence rate of ECM and its derived types of mycorrhizas and the species richness of plant clades that harbor these symbiotic systems are not coincidental. This observation becomes particularly striking when compared to mycoheterotrophy, another type of plant-fungus symbiosis, which will be discussed below. Because ascomycetous and basidiomycetous mycorrhizal fungi have a much higher host specificity than glomeromycetous fungi (Horton and Bruns 1998; Newton and Haigh 1998; Bidartondo and Bruns 2002), diversification of the plant hosts had likely in turn driven the speciation rate of the fungal symbionts. This coevolutionary arms race probably explains the large number of Basidiomycetes that are ectomycorrhizal today (Molina et al. 1992). In comparison, AM has obviously contributed very little to the diversification of glomeromycetous fungi, and the relatively low host specificity of these fungi may be to blame.

Mycoheterotrophy

Mycoheterotrophy represents a shift of balanced mutualistic symbiosis between plants and fungi toward an exploitative use of mycorrhizal fungi by plants that are no longer fully photosynthetic (Leake 1994). It is clearly a derived condition in mycorrhizal evolution. In our survey, we found that mycoheterotrophy had evolved many times independently in land plants, in the following families: Aneuraceae, Podocarpaceae, Petrosaviaceae, Burmanniaceae, Triuridiaceae, Corsiaceae, Orchidaceae, Ericaceae (Monotropoideae), Gentianaceae, and Polygalaceae (Fig. 1). The mycoheterotrophy in the moss genus *Buxbaumia* needs more thorough investigation (Leake 1994). In addition, gametophytes of *Lycopodium*, *Psilotum*, and *Botrychium* are also mycoheterotrophic (reviewed by Brundrett 2002). However, it has been suggested that mycoheterotrophy in these latter cases and most species of Orchidaceae may be different from that in other plant groups mentioned above (Bidartondo 2005) because these plants only engage in mycoheterotrophy for a part of their life cycles during establishment, and they are photosynthetic for the rest of their life cycles and enter mutualistic symbiosis with mycorrhizal fungi.

The independent evolution of mycoheterotrophy in many unrelated lineages of land plants is further underscored by the fact that it evolved repeatedly from AM and ECM and ECM-derived types of mycorrhizas (Fig. 1).

Hence, evolution of mycoheterotrophy reinforces the evolutionary parallelism commonly seen in mycorrhizal evolution, which has dominated evolution of ECM as discussed above and loss of mycorrhiza to be discussed below. Although one may think that an exploitative relationship such as mycoheterotrophy can be evolutionarily unstable, which seems to be supported by the general paucity of species in most clades of mycoheterotrophic plants (Leake 1994), this unique type of interaction among more than two species of very different modes of nutrition uptake (autotrophy and heterotrophy) might have played a special role to facilitate some major transitions during land plant evolution. In the case of lycopophytes and ferns, mycoheterotrophy probably helped to ease the transition from a gametophyte generation-dominant life cycle in bryophytes to a sporophyte generation-dominant life cycle in vascular plants. For most Orchidaceae, mycoheterotrophy has perhaps alleviated the problem of extremely small size of the seeds, which can be advantageous for dispersal but at the same time, limits nutrition packaging for the next generation, and thus has probably contributed significantly to the success of the family. These two examples once again highlight the important roles played by fungi not only in the origin, but also in many subsequent radiations of land plant evolution.

Many independent losses of mycorrhiza in land plants

Many families of land plants have not been found to form mycorrhizas with fungi in their natural habitats. In liverworts, no fungal association has been observed in Blasiaceae, Ricciaceae, Metzgeriaceae, Radulaceae, Porellaceae, Jubuliaceae, Lejeuneaceae, or Herbertaceae. In pteridophytes, species in Isoetaceae and Azollaceae are nonmycorrhizal. Similarly in angiosperms, species in Nymphaeaceae, Butomaceae, Limnocharitaceae, Cyathaceae, Cannaceae, Loranthaceae, Loasaceae, Lentibulariaceae, Menyanthaceae, Adoxaceae, Erythroxylaceae, and Bataceae are nonmycorrhizal. In addition, nonmycorrhizal species occur together with mycorrhizal species in many families, and approximately half of the ten or more species examined in the following families are nonmycorrhizal: Geocalycaceae, Jungermanniaceae, Lycopodiaceae, Hymenophyllaceae, Gleicheniaceae, Pteridaceae, Adiantaceae, Aspleniaceae, Thelypteridaceae, Dryopteridaceae, Polypodiaceae, Cyperaceae, Polygonaceae, Amaranthaceae, Caryophyllaceae, Crassulaceae, and Brassicaceae (Table 1, Fig. 1). The fact that these families are deeply embedded among mycorrhizal families and are not closely related to each other provides convincing evidence that these plants lost their ability to form mycorrhiza independently.

There are two interesting features for phylogenetic distribution of nonmycorrhizal plants. One is that leafy liverworts and pteridophytes in general tend to have a high concentration of nonmycorrhizal species. Of course, mosses, as an entire clade, lack mycorrhiza as well (Read et al. 2000) except *Takakia* (Boullard 1988). Gymnosperms, on the other hand, are all mycorrhizal and almost

all obligately mycorrhizal. Angiosperms generally are also mycorrhizal, and have only a few groups that have a high percentage of nonmycorrhizal species, alismatids (including Araceae according to Stevens' (2004) new classification system, see Fig. 1b), Cyperaceae, caryophyllids, and Brassicaceae. This feature may be related to the fact that early land plants had not fully adapted to the symbiotic system with the fungi. Indeed, these plants generally have the *Paris*-type AM, which lacks well-developed systems of intercellular hyphae and do not always form arbuscules (Read et al. 2000). It will be interesting to see if future studies can demonstrate that a simpler genetic system is behind this rather unstable symbiotic relationship in basal land plants. The other feature is that almost all nonmycorrhizal plants are derived from ancestors that engaged in AM symbiosis. In the several families where ECM and ECM-derived mycorrhizas dominate or account for a large percentage, e.g., Pinaceae, Orchidaceae, Ericaceae, Myrtaceae, Salicaceae, Fagales, and Cistaceae, very few species are nonmycorrhizal. This feature is perhaps related to the highly specialized nature of the ECM symbiosis.

As to the mechanisms responsible for mycorrhizal loss, Trappe (1987) noticed several characters that tend to be shared by nonmycorrhizal species, and his observations still hold true here. First, many nonmycorrhizal vascular plants grow in aquatic or wetland habitat. In these environments, both nutrients and water supplies are not as limited as in the typical terrestrial environment. Hence, the plants can develop independence from the fungal symbionts and reduce the carbon cost that would normally be provided to the fungal partners in exchange for nutrients and water. The loss of mycorrhiza in alismatids and other aquatic plants likely occurred through this mechanism. Second, species that grow in nutrient-rich environments tend to be nonmycorrhizal. The ruderals in caryophyllids, Brassicaceae, and Crassulaceae, and the spring ephemerals in Ranunculaceae, Papaveraceae, and Saxifragaceae belong to this category. Third, the plants that have a long, fine, and highly branched root system with well-developed root hairs also have a high tendency to become nonmycorrhizal. Cyperaceae and the ruderals perhaps developed independence from fungal symbionts through this route. It has been suggested that root hairs and mycorrhizal fungi were two alternative mechanisms for plant nutrient uptake (Baylis 1970; Koide 1991). If a plant can absorb sufficient nutrients through its own root hairs, any genetic changes preventing the formation of mycorrhiza with fungi would be favorably selected. Besides these three observations made by Trappe (1987), we also noticed that many liverworts that lack fungal association are leaf and bark epiphytes, e.g., Radulaceae, Jubulaceae, Porellaceae, and Lejeuneaceae. A possible explanation could be that fungal development is thwarted by defense mechanisms of the plant on which these epiphytes live.

Areas of further study

This study and those by Trappe (1987) and Harley and Harley (1987) represent the three most extensive surveys of mycorrhizal occurrence in land plants, but the total number of species included in the three studies is only slightly over 10,000 (assuming that there is little overlap among the three surveys), which is about 3% of all listed land plant species that live on our planet. As can be seen from Table 1 and Fig. 1, for most plant families we have knowledge of the mycorrhizal status for only one or a few species. Hence, the first area that deserves more attention in the future is the investigation of mycorrhizal status of more species. From this study and those by Trappe (1987) and Harley and Harley (1987), as well as several reviews published earlier on this topic (Pirozynski and Malloch 1975; Malloch et al. 1980; Selosse and Le Tacon 1998; Read et al. 2000; Brundrett 2002), it is clear that mycorrhizas were instrumental in the origin and subsequent diversification of land plants and are continuing to play a vital role in maintaining floristic diversity and ecosystem function on earth. Thus, mycorrhizal symbiosis should be viewed as an integral part of any floristic, ecological, or evolutionary studies in the future.

Besides the general increase of mycorrhizal research, a few specific areas should be pursued. First, more basal land plants should be investigated, as they occupy an especially important position in our understanding of the origin of mycorrhizal symbiosis in land plants. Despite several studies on basal land plants (Pocock and Duckett 1985; Duckett et al. 1991; Read et al. 2000), our knowledge on phylogenetically critically positioned taxa such as Treubiaceae, many simple thalloid liverworts, mosses, and some hornworts, remains fragmentary. In this regard, mosses deserve special attention, as they represent the only major clade of land plants that is nonmycorrhizal (Read et al. 2000), a situation which by itself is very puzzling. Several basal moss lineages such as Andreaeaceae, Tetraphidaceae, Polytrichaceae, Buxbaumiaceae, and Diphysciaceae all grow on nutrient-poor, sandy soil or rocks. It will be interesting to know how they manage to grow on these poor substrates if they are truly nonmycorrhizal. *Takakia*, a sister group to all other mosses, is reported to be mycorrhizal (Boullard 1988) and grows on thin soil and rocks (Gao 2000). Second, several early-diverging lineages of angiosperms, Amborella, Austrobaileyales, Chloranthaceae, and magnoliids should be investigated; the information on their mycorrhizal status is currently lacking. Even when Trappe's (1987) survey is included, our knowledge of these plants is still quite poor. A focused study on these plants will fill an important gap in our understanding of mycorrhizal evolution in early angiosperms. Finally, as we learn more from studies of model organisms such as legumes (Stracke et al. 2002; Liu et al. 2003; Ane et al. 2004; Demchenko et al. 2004; Levy et al. 2004), characterization of molecular aspects of mycorrhizas in nonmodel organisms will significantly expand the dimension and depth of our knowledge of this important symbiotic system. In summary, the mycorrhizal research

conducted over the last several decades has brought this long neglected field into mainstream biology, and future research will undoubtedly further enhance our understanding of this important biological interaction and its impact on the evolution of both plants and fungi, as well as the establishment and functioning of the terrestrial ecosystem.
